

TO MY FAMILY

In the simulation we tried a method of analysis that has not hitherto been used in a molecular dynamics simulation to our knowledge. The method looks at the simulation results in momentum space and shows how a distribution of defects may be obtained by fitting various models to the simulation results. We adopted this method as it is exactly how the defect concentrations from neutron scattering are obtained so it affords a comparison between simulation results and experiment that is much more direct than the comparisons used before.

Finally, the material is organised as follows: Chapters 2 and 3 describe the lattice gas model, the theory we used on it and the results we obtained. Chapters 4 and 5 contain a description of the molecular dynamics technique, the interionic potential that we found for lead fluoride and the results of the lead fluoride simulation. Chapter 6 contains our conclusions.

However, we can use the Padé approximant technique successfully applied by Stell and Wu (1975) to a system of charged spheres. This technique is a method of interpolation between the low and high concentration limits so that our expression for the free energy should be valid even at the concentrations encountered in fastionics.

2B. Diagram Theory

As mentioned in the preliminary, we need to calculate the free energy of our system of charged mobile defects with the excluded site property. We split the free energy into two constituents, one, F_0 being that of a lattice gas whose only interaction is that of site exclusion, the other, F_c , the contribution from Coulomb interactions. In this chapter we show how to find a diagrammatic series for F_c in increasing order of electronic charge to order e^6 . Our zeroth order term is the free energy of charged particles in a continuum calculated using Debye-Hückel (D-H) theory. We describe how the discrete nature of our system can be taken into account through terms of increasing order in e and how charge fluctuations ignored by D-H theory can be included.

We commence by obtaining a diagrammatic series in continuum theory for the grand canonical partition function Ξ from which the free energy series may be obtained. The free energy series is then modified to allow for the discrete nature of our lattice gas. We believe that the continuum theory we use should be valid for the discrete case but we present it as continuum theory since the methods are standard and have been described by Hansen and McDonald (1976).

We have also calculated the cohesive energy directly from the potential. It is the total internal energy consisting of the Coulomb energy (found from the Madelung sum) and the short range contribution found from summing the interaction energy out to nearest neighbours.

This is a very useful test particularly of the ionicity of the solid.

4C. Tests of Stability

In this section we describe how, having obtained a potential by fitting to the lattice and static dielectric constants, we apply various tests to the potential. We show how in this study the potential had to be modified to avoid an instability which resulted in the longitudinal Raman mode at the Brillouin zone boundary (hereafter simply called the boundary Raman mode) having a negative squared eigen-frequency.

As we commented in section B, it is essential to obtain approximately the right value for the Frenkel energy for a static lattice E_0 . Thus the first test we applied was to use the HADES (Harwell Automatic Defect Evaluation System) program to calculate E_0 . This is a program designed to evaluate defect energies in a static lattice. HADES divides the simulated material into two regions; an inner region (region I) containing Ca 100 ions where the ions are represented explicitly on a lattice using the interionic potential under test and an outer region (region II) which is treated as a matched dielectric continuum. The defect energies required are calculated by allowing the ions in region I to

relax to equilibrium and taking account of displacements in region II obtained using macroscopic polarisation and elastic fields. The programme has been described in detail by Lidiard and Norgett (1972) and Norgett (1974). We used HADES to find the energy required to take an anion off the regular site and put it on the empty cube centre site, to check that the interstitial is stable at the cube centre site. This can be done by using the HADES program to calculate the energies (relative to the energy of the perfect lattice) of interstitials which are slightly displaced from the cube centre. Another check is that the interstitial is stable against interstitialcy motion in which a lattice ion is displaced into an adjacent interstitial site (Catlow and Norgett 1973). We also look at vacancy migration energies, the energy barrier against movement of a vacancy at one lattice site to a nearest neighbour lattice site. Clearly a potential with large energy barriers against interstitialcy motion and vacancy migration in the static lattice is less likely to create problems in the molecular dynamics simulation at finite temperatures.

The final test we consider necessary is that the potential should show up no instabilities when evaluating the phonon spectrum for the regular lattice.

Having detailed the tests that we consider necessary to obtain an acceptable potential we now describe how a potential we obtained using the approach described in section B failed the final test, that of giving stable phonon modes, and how we modified it accordingly.

We found that by making all the assumptions described in section B concerning the parameters, A_{++} , C_{++} , ρ_{++} , A_{--} , C_{--} , ρ_{--} and C_{+-} and fitting A_{+-} and ρ_{+-} to a and ϵ_r that we had a potential which gave good values for the elastic constants, cohesive energy and Frenkel energy. It also showed none of the instabilities tested for with the HADES program. However when we evaluated its phonon spectrum using a standard programme we found that the boundary Raman mode in the $(1\ 0\ 0)$ direction (or $(0\ 1\ 0)$ or $(0\ 0\ 1)$ directions by symmetry) had a negative eigenvalue (square of the eigenfrequency) whose magnitude was approximately that of the square of the experimental frequency (Dickens and Hutchings 1978). Thus not only was an instability present, but it was also severely unstable. It is worth noting that this soft mode is an indication of the weakness of the fluorite structure in these directions and the same mode has been observed to show a tendency to soften in SrCl_2 (Dixon 1980, private communication). Its eigen-vectors show that the anions are displaced along adjacent parallel lines in the fluorite structure and that the cations are not displaced at all.

The way we chose to cure the instability was to fit another of the nine parameters in the potential so that in addition to the correct ϵ_r and a we would have a positive eigenvalue W_R^2 for the boundary Raman mode.

We were able to do this by choosing the parameter C_{--} to be the extra parameter fitted to experiment. The reason for this was that equation (4.10) shows that only the cation-

anion short range interaction contributes to the expression for ϵ_r and it comes in the combination $(\frac{2}{r} \frac{\partial \psi_{+-}^{SR}}{\partial r} + \frac{\partial^2 \psi_{+-}^{SR}}{\partial r^2})$. From (4.26) below we see that if nearest neighbour interactions only are considered for the short range potential, the cation-anion short range interaction contributes to W_R^2 in exactly the same combination. Therefore it is pointless to alter W_R^2 by fitting the cation-anion parameter C_{+-} in addition to A_{+-} and ρ_{+-} as we have to obtain the correct dielectric constant which fixes the combination $(\frac{2}{r} \frac{\partial \psi_{+-}^{SR}}{\partial r} + \frac{\partial^2 \psi_{+-}^{SR}}{\partial r^2})$. As the cations are not displaced in this mode, there is no point either in altering the cation-cation interaction. We are therefore left with the short range anion-anion interaction. We chose C_{--} rather than A_{--} and ρ_{--} because it is not well understood so that the value obtained by Catlow and Norgett (1973) for fluorine ions in fluorites is not as reliable as their values for A_{--} and ρ_{--} .

We calculated W_R^2 as follows. The phonon modes for a perfect lattice are found from the equation of motion in the harmonic approximation

$$\omega^2 \underline{\underline{m}} \underline{u}_q = \underline{\underline{M}}(q) \underline{u}_q \quad (4.19)$$

Here \underline{u} is a column matrix whose elements are the displacements of ions on each sublattice, $\underline{\underline{m}}$ is a diagonal matrix with the mass of the ions on each sublattice and $\underline{\underline{M}}$ is the force constant matrix (Cochran 1966). The Raman mode that we want is longitudinal and we take it as being parallel to the x direction (1 0 0) although y or z could equally well be chosen by symmetry. Thus it is only necessary to diagonalise

where

$$\psi(r) = \text{potential due to the gaussian charge}$$

$$\rho(r) = \left(\frac{p}{\pi}\right)^{3/2} e^{-pr^2} \quad (4.29)$$

$$= \frac{1}{r} \operatorname{erf}(\sqrt{p}r) \quad (4.29a)$$

and Z_K is the charge of the ion K in the unit cell in units of the electronic charge $|e|$. Then

$$\varphi^{KK'}(r) = \left[\frac{4\pi}{\Omega} \sum_{\mathbf{g}} \frac{e^{-g^2/4p}}{g^2} e^{i\mathbf{g}\cdot\mathbf{r}} + \frac{1}{r} \operatorname{erfc}(\sqrt{p}r) \right] \frac{Z_K Z_{K'} e^2}{4\pi\epsilon_0} \quad (4.30)$$

where Ω is the volume of the crystal, \mathbf{g} is a reciprocal lattice vector. The reason for this manipulation is that by a good choice of the convergence parameter p the series can be made to converge very quickly. p is fixed such that the nearest neighbour terms summed for the reciprocal space series and for the real space series are of approximately the same magnitude.

When finding the Coulomb contribution to the matrix element we do have one useful simplification:

$$C^{xx}(K K 0) - \sum_{K'} C^{xx}(K K' 0) = 0 \quad (4.31)$$

by applying Laplace's equation

$$\nabla^2 \varphi_c = 0 \quad (4.32)$$

Then we find

that this would be sufficient to annul the instability. Unfortunately the resulting potential was found to be unstable with respect to interstitial migration so we were forced to alter A_{--} and ρ_{--} to avoid this. However we did find that only slight adjustments to A_{--} and ρ_{--} were necessary to give a potential that is specified in section D.

4D. Potential Chosen

In table 1 we list the nine parameters of the short range potential that we found.

In table 2 we give the values of: the Frenkel energy E_0 , the interstitial migration energy, ξ_i , the vacancy migration energy, ξ_v , the Raman zone boundary frequency, ω_R^2 , the cohesive energy, ξ_c and the elastic constants C_{11} , C_{12} , C_{44} . Experimental measurements of these parameters are also shown. It is clear from table 2 that we have satisfactory agreement for all the parameters we have calculated although the agreement for the interstitial and vacancy migration energies is poor. However overall the agreement was good enough for us to try the potential in the molecular dynamics simulation programmes with the results outlined in Chapter 5.

CHAPTER 5
MOLECULAR DYNAMICS RESULTS

5A. Real Space Analysis

We described the technique of the molecular dynamics simulation in section 4A. Now we indicate how certain quantities relating to the disorder can be obtained from the simulation, discuss our results and compare them where possible with experiment. We give in table 3^{*} details of temperatures at which we made runs, the lengths of each run, ΔR , and the lattice constant a at that temperature (giving the length scale). The simulations were all done for a box of ninety six particles at a pressure of about 0 atmospheres corresponding to very low ie. atmospheric pressure. The time step used was $\Delta t = 10^{-14}$ s.

(i) Time Dependent Behaviour

As we commented in section A, the simulation can either be used to look at the behaviour of the ions as a function of time, measured in discrete time steps Δt , or by averaging over the system behaviour at different time steps to obtain static equilibrium averages. Here we look at the time dependent behaviour since we can obtain from this analysis values of the diffusion coefficient D_d and the conductivity σ which may be compared with experiment. We also obtain an estimate of the defect concentration although we consider another way of finding this important parameter in section B. Additionally we have information about the directions for which the hops are taking place.

* on page 68

First of all it is necessary to find the position of the underlying regular lattice. We use the cation positions for this as we have been able to check that, in agreement with experiment (see the introduction), the cations do not diffuse. This check was done by calculating the time dependent mean square displacement

$$\langle r_{\alpha}^2(t) \rangle = \frac{1}{N_{\tau}} \sum_{\tau} \frac{1}{N_{\alpha}} \sum_i \left[r_{i\alpha}(t+\tau) - r_{i\alpha}(\tau) \right]^2 \quad (5.1)$$

where $r_{i\alpha}(t)$ is the position of the i th ion of species α at time t . The sums go over time origins τ and N_{τ} , N_{α} are the numbers of time origins and ions of species α respectively (see Dixon and Gillan 1980). At long times $|t|$ we have (Sangster and Dixon 1976)

$$\langle r_{\alpha}(t)^2 \rangle \rightarrow B_{\alpha} + 6 D_{\alpha} |t| \quad (5.2)$$

where D_{α} is the self diffusion constant of species α and B_{α} is a constant. Thus if D_{α} is zero, the cations are not diffusing and this is what we found at all temperatures. The cations are however vibrating about their regular sites and furthermore the cation sublattice as a whole is moving. (The sublattice recoils each time an anion hops by conservation of momentum). Therefore it was necessary to calculate the mean vector position for each simulation run and to average these positions to construct the position of the lattice.

Once the regular lattice sites have been established, it is possible to obtain a hopping catalogue for the anions. This catalogue records when an anion leaves a sphere of radius $d = a/6$ (a is the lattice constant) whose centre is at the anion regular site. The catalogue also indicates when that

anion enters a sphere of the same radius surrounding another regular site. The two events constitute a hop. It is clear that such a method of analysis assumes that there are no other sites to which the hops are made as the hops only occur between regular sites. The method is vindicated by the fact that and (1980) found using precisely this form of analysis on an SrCl_2 simulation, that when the radius of the sphere was decreased by a factor of two, the number of hops recorded only changed by 25%. Since the volume of the sphere would have been decreased eightfold when d was reduced by two, this suggests that most of the hops are taking place between sites within $a/12$ of the regular site. Furthermore none of the hops recorded by the catalogue last more than a few vibration periods indicating that none of the ions are lingering on sites between the regular sites.

The hopping catalogue can first of all be used to find the directions of the hops. Three kinds of hop were found: between nearest sites along a cube edge (direction (1 0 0)) (91.5%), along a cube face diagonal ((1 1 0)) (8%) and along a cube body diagonal (.5%). The percentages shown are percentages of hops in each direction noted from a simulation run at 1000K; the figures indicate very clearly that by far the greatest number of hops is along the (1 0 0) direction. This is in complete agreement with and (1980).

These percentages may also be used to evaluate the mean square value of the hopping distance, $\overline{G_0^2}$. Thus

$$\overline{G_0^2} = \sum p r^2 = \frac{1.09 a^2}{4} \Big|_{T=1000K} \quad (5.3)$$

Here the sum is taken over the three different values of r for each of the three directions specified above, r is the nearest neighbour distance in each direction and p is the percentage of hops in that direction. The figure of 1.09 is obtained from the percentages quoted above. From the total number of hops per unit time we obtain the mean rate ν at which each anion executes hops. If we assume that the directions of hops are statistically independent, then we can obtain the anion diffusion constant

$$D_- = \frac{1}{6} \overline{r^2} \nu \quad (5.4)$$

(Corish and Jacobs 1973).

We used this analysis to obtain D_- at 400K, 600K, 800K, 900K and 1000K; our results are shown in table 4. It is interesting to see that we obtain quite reasonable agreement with experimental values for D_- that are also shown in table 4. This we feel is a good indication that our simulation is producing a good representation of lead fluoride, bearing in mind the slightly arbitrary nature of the methods chosen to find the potential to be used in the simulation.

We may also evaluate the dc conductivity from the simulation using the Nernst Einstein relation

$$D_- = \frac{f_H k_B \sigma T}{\rho_- e^2} \quad (5.5)$$

Corish and Jacobs (1973).

Here f_H is the Haven ratio, k_B is Boltzmann's constant, e the electronic charge and ρ_- the density of mobile ions given by

b Carr et al. (1978)

$$\rho_- = 8/a^3 \quad (5.6)$$

where a is the lattice constant. (f_u is defined by (5.5)).

We have shown our results for σ in table 4 which we calculated using (5.5) and the values of D given in table The Haven ratio was set equal to unity as it is not clear precisely which value to take and it is known that it should not differ from unity by more than a factor of 30%. (Corish and Jacobs 1973).

We see from table 4 that we also obtain approximate agreement with experiment though this is not such a reliable comparison because of uncertainties over the Haven ratio. However table 4 does show that the simulated lead fluoride has the main characteristic of a fastionic, viz. a sharp increase in conductivity over a relatively narrow temperature range. This temperature range lies between 600K and 800K and may be compared with the fastionic transition temperature T_s found experimentally for lead fluoride of 705K (Derrington et al 1976). We have not examined more precisely the temperature range over which the transition occurs in our simulation as we are more interested in the qualitative nature of the disorder above the transition, and do not consider our simulation would give especially good results for the behaviour at the transition.

Finally we look at the defect concentration d_c . A defect, as we have already indicated in the introduction, is a vacancy or an interstitial for the fluorites. The existence

of vacancies and interstitials may be found by looking at correlated sequences of hops. A correlated sequence is when a hop occurs from one site (1) to another (2), from site 2 to site 3 and so on.

We define the time at which a hop from site 1 to site 2 takes place as the mean of the times at which the anion leaves site 1 and arrives at site 2, and specify the hop from site 1 to site 2 by the ordered pair (1, 2). Then if the time t at which (1, 2) takes place is before the time t^1 at which (2, 3) takes place, we may consider this as indicating the presence of an interstitial on site 2 for time $t-t^1$. Similarly if $t-t^1$ is negative, this corresponds to a vacancy at site 2.

We can count the interstitials and vacancies from a pictorial representation in which the hopping events are represented as points on a line parallel to a time axis and the correlation arrows are drawn to connect the points. An arrow pointing parallel to the positive direction of the time axis indicates that an interstitial is present for the time represented by the length of the arrow. Likewise, an arrow pointing along the negative direction of the time axis indicates that a vacancy is present. The total number of vacancies plus interstitials is found at any instant by counting the number of correlation lines that cut the line perpendicular to the time axis, that intersects the time axis at that instant. We find the average defect concentration namely the number of vacancies (or interstitials) per site by averaging the number of vacancies (or interstitials) over the run. By charge neutrality, the numbers of vacancies and

PART II

A NUCLEAR QUADRUPOLE INTERACTION IN ORDERED MAGNETS

validity of our results in view of the other approximations made (which are discussed in that section).

However, it is interesting to note that if account were taken of the orbital contribution to the susceptibility, our theory would apply to examples where orbital momentum cannot be neglected.

Localised model predictions for $X_{nn}^{xx}(T)$, $X_{nn}^{zz}(T)$ and $\tilde{X}(T)$

Fig.1.

$$\langle (S^z)^2 \rangle = \frac{\sum_{S^z=-S}^S (S^z)^2 e^{-\beta J(c) \langle S^z \rangle S^z}}{\sum_{S^z=-S}^S e^{-\beta J(c) \langle S^z \rangle S^z}} \quad (3.55)$$

Equations (3.45) and (3.55) show that $\tilde{\chi}$ is positive and that it varies as $\langle (S^z)^2 \rangle$ and hence linearly with t .

If we use the interacting molecular field of section A we find that the dimensionality of our system comes in explicitly and we obtain different (and incorrect) results in three dimensions. The discrepancy can be explained by scaling theory as we discuss below.

We use equation (3.16) and

$$\chi_{\underline{k}}^{zz} = \frac{\tilde{\chi}}{k^2 + K_0^2} \quad (3.56)$$

(eg. Marshall and Lovesey 1971) where k is the inverse correlation length

In d dimensions we find for nearest neighbour exchange interactions

$$\tilde{\chi} = \frac{1}{N} \sum_{\underline{k}} (\chi_{\underline{k}}^{xx} - \chi_{\underline{k}}^{zz}) \quad (3.57)$$

$$\approx \frac{N \sum_{\underline{k}} K_d \int_0^{K_0} dk \, k^{d-1} \left[\frac{1}{k^2} - \frac{1}{k^2 + K_0^2} \right]}{a^2 J_0} \quad (3.58)$$

Here K_d is the appropriate angular factor (eg. $K_3 = 4\pi$), J_0 the exchange constant, a is the lattice parameter and the inverse correlation length is given by its molecular field approximation

$$K_0^2 = \frac{2t}{a^2} \propto t^{2-\nu} \quad (3.59)$$

The integral has been performed assuming that the dominant contribution is from the low k values.

In three dimensions,

$$\tilde{\chi} \propto K_0 \tan^{-1} k_0 / K \sim e^{\nu} \sim L^{1/2} \quad (3.60)$$

(We take the classical value for ν)

In just over four dimensions,

$$\tilde{\chi} \propto K_0^2 \sim t \quad (3.61)$$

(at exactly four dimensions there will be logarithmic corrections (Ma 1976))

The result for four dimensions agrees with the real space simple molecular field calculation (after equation (3.55)), whereas the result for three dimensions does not.

This discrepancy is due to the fact that the scaling relation between ν and β (Stanley 1971), equation (3.62) below involves the dimensionality d and is only satisfied with classical exponents ($\nu = \beta = \frac{1}{2}, \eta = 0$) at $d = 4$:

$$2\beta = \nu(d - 2 + \eta) \quad (3.62)$$

3C. The Itinerant Model

As discussed in the introduction, it is especially useful to have an estimate of the magnitude of the pseudoquadrupole effect in iron and nickel, at both host metal nuclei and at impurities in very dilute alloys. In this section we show how such an estimate can be obtained using a simple model to calculate the susceptibilities based on Kim, Kubo and

Izuyama (1963).

The magnetism of iron and nickel is due to d electrons whose spins are aligned by exchange interactions. A large body of experimental evidence (reviewed by Herring (1966)) indicates that d electrons are itinerant. Thus any theory of magnetism in these metals must be founded on band theory.

Such a theory has been given by Kim, Kubo and Izuyama (1963), (KKI). Lowde and Windsor (1970) have shown that this theory provides a good description of the magnetism in nickel. Doniach (1968) has also argued that the RPA is a reasonable approximation to the ground state in nickel but he comments that in iron many body corrections are likely to be present. Recent theories have been shown to give an improved description of both the ground state and behaviour at finite temperatures, especially in iron (for reviews see Pettifor (1980) and Moriya (1979)). We will however, use KKI's formulation as our results do not appear to justify a more accurate theory (see discussion at the end of this section).

KKI calculate the spin susceptibilities using a single band tight binding approximation. By ignoring the overlap between Wannier functions centred at different lattice sites compared with the overlap for the functions at the same site, they are able to write the susceptibilities in terms of 'reduced' susceptibilities $\chi'^{\mu\nu}$

$$\chi_{\underline{k}}^{\mu\nu} \approx |F(\underline{k})|^2 \chi'_{\underline{k}}^{\mu\nu} \quad (3.63)$$

$$= |F(\underline{k})|^2 \sum_{\underline{k}', \underline{k}''} \langle\langle a_{\underline{k}+\underline{k}'}^{\dagger} \sigma_{\underline{k}}^{\mu} ; a_{\underline{k}+\underline{k}''}^{\dagger} \sigma_{\underline{k}}^{\nu} \rangle\rangle_{\omega} \quad (3.64)$$

after (3.65).

ν is given by the conditions

$$\Delta = \frac{\nu \xi}{N} \sum_{\underline{k}} (f_{\underline{k} \uparrow} - f_{\underline{k} \downarrow}) \quad (3.71)$$

and

$$\nu = \frac{1}{\Gamma_{\underline{k}=0}^{+-}} \quad (3.72)$$

(3.72) is the condition for a Goldstone mode to exist (for a discussion see Kubo and Izuyama (1969)).

At $T = 0$ the contributions to Γ^{+-} arise from terms when $f_{\underline{k} \downarrow} = 1$ and $f_{\underline{k} + \underline{k}' \uparrow} = 0$ and terms in which $f_{\underline{k} \downarrow} = 0$ and $f_{\underline{k} + \underline{k}' \uparrow} = 1$. These are shown in figure 2a. $\Gamma_{(- -)}^{++}$ is due to transitions within an up (or down) spin band as shown in figure 2b.

For an order of magnitude estimate we use parabolic bands, an approximation which may be justified for nickel where there are few holes per atom and these lie at the top of the band where the density of states is a minimum. Clearly the approximation is much less justified for iron but as the use of RPA theory is also doubtful (as we have already mentioned) there seems no point in attempting a better calculation.

In this case the following expressions are obtained for the correlation functions.

$$\begin{aligned} \Gamma_{\underline{k}}^{+-}(\omega=0) = & \frac{\xi m^* \nu}{N 4 \pi^2 \hbar^2} \left\{ \left[\frac{k_{F \downarrow}^2}{2k} - \frac{(\Delta' + k^2)^2}{8k^3} \right] \log \left| \frac{2k k_{F \downarrow} + \Delta' + k^2}{2k k_{F \downarrow} - \Delta' - k^2} \right| \right. \\ & - \left[\frac{k_{F \uparrow}^2}{2k} - \frac{(\Delta' - k^2)^2}{8k^3} \right] \log \left[\frac{2k k_{F \uparrow} + \Delta' - k^2}{2k k_{F \uparrow} - \Delta' + k^2} \right] \\ & \left. + k_{F \downarrow} \frac{(\Delta' + k^2)}{2k^2} - k_{F \uparrow} \frac{(\Delta' - k^2)}{2k^2} \right\} \quad (3.73) \end{aligned}$$

Contributions to χ_{nn}^{xx} Contributions to χ_{nn}^{zz}

Fig. 2a.

Fig. 2b.

Other authors (Wakoh et al (1971)) have found that D_c is much smaller than the experimental value D_e , as we do (using the parameters described below). This may be attributed to the use of the extreme tight binding approximation in which the electron-electron interaction is assumed site diagonal in a Wannier representation (Edwards (1980)). However, there is also considerable experimental uncertainty about D_e (Louwde (1979), private communication).

To make estimates of D_c , $v(T = 0)$ and $v(T = T_c)$ we used the following parameters which we obtained from experiment: the number of holes in the up and down spin bands (which for nickel is found from the electron g factor and the saturation magnetisation (Kittel 1971)) and Δ for nickel (for iron it is determined by the difference between the up and the down spin bands - see figure 2a). We evaluated m^* from the experimental measurements of the electronic specific heat C_{e1} which are quoted in Kittel (1971) using

$$C_{e1} = \gamma T = \frac{1}{2} \pi^2 N k_B \frac{T}{T_F} \quad (3.77)$$

where T_F is the Fermi temperature

It is necessary to assume that the d band holes would dominate C_{e1} and additionally in iron that the contribution from spin down band holes can be neglected. The values we took for these parameters and references are given in table 1.

We find the itinerant susceptibilities from equations (3.67) and (3.69) and our expressions for the correlation functions for parabolic bands, equations (3.73) and (3.74). The itinerant susceptibilities, χ_{nn}^{xx} and χ_{nn}^{zz} are defined by

$$\chi_{nn}^{xx} = \sum_{|k| < k_m} \chi_k^{xx} \quad (3.78)$$

Fig. 3a

$$\chi_k^{\alpha\alpha} \approx \int \frac{(n_\downarrow - n_\uparrow)}{Dk^2} \quad (3.81)$$

where D is the spin wave stiffness. We call this approximation to $\tilde{\chi}$, $\chi_{A(i)}$ where we use $D = D_c$ (equation 3.76) and $\chi_{A(ii)}$ where $D = D_e$, the experimental spin wave stiffness.

$\chi_{A(i)}$ and $\chi_{A(ii)}$ are given in table 4 which includes estimates $\tilde{\chi}_{mf}$ obtained from molecular field theory using equations (3.16), (3.21), (3.22), (3.25) and

$$\tilde{J}(0) = \frac{S(S+1)}{3k_B T_c} \quad (3.82)$$

This table shows that $\chi_{A(i)}$ is a good approximation to $\tilde{\chi}_{nn}(T=0)$, making a check on our results for the latter. However, $\chi_{A(ii)}$ considerably underestimates $\tilde{\chi}_{nn}(T=0)$ owing to the large discrepancy between D_c and D_e . We see that the molecular field theory calculation gives good agreement for nickel but not for iron.

We then go on to estimate P_{pq} for the pure metal using equations (3.16) and (2.44). In (2.44) the saturation values of the magnetisation were substituted for M_0 ; these are 0.604 Bohr magnetons for nickel and 2.22 Bohr magnetons for iron (Martin(1967)). The other parameters we used to obtain A are given in table 5.

Our values are compared with experimental measurements of the quadrupole parameter P for iron in table 5. It is clear that our estimate for the pseudoquadrupole parameter P_{pq} is down by about two orders of magnitude compared with

the experimental parameter:

$$P_e = P_{pq} + P_q \quad (3.83)$$

P_q is due to the electrostatic quadrupole moment of the nucleus and is given by,

$$P_q = \frac{3e^2 Q q}{4\pi (2I-1)} \quad (3.84)$$

for a nucleus of quadrupole moment Q (e is the electronic charge) (Stone 1980) where q is the electric field gradient at the nucleus. Thus, even if our model were to significantly underestimate P_{pq} (we have no reason to believe that it would), it appears unlikely that the pseudoquadrupole effect would make a large contribution to P .

There is considerable interest in the quadrupole effect at impurities in iron and nickel as described in the introduction. For here there may be magnetically induced field gradients due to the rather subtle mechanisms of unquenched orbital momentum and magnetostriction (Gehring 1974). We therefore estimate the size of the splitting for impurities where experimental data is available. These are the effectively non magnetic impurity, iridium and the magnetic impurity, cobalt. The results are in table 5.

We treat iridium as a non magnetic impurity and use the theory of section D, Chapter 1 to find P_{pq} although here there is evidence for a small local moment and a virtual bound state in both Ni(Ir) (Demangeat (1975) I) and Fe(Ir) (Demangeat (1975) II). Thus the local susceptibility may be significantly affected making our assumption (in Chapter 1, section D), that P_{pq}^I given in the table provides an upper

obtained using Wolfram's (1961) theory. He calculated the susceptibility using essentially an extended version of KKI. Also Campbell and Gomés (1967) find an expression for the local susceptibility in an appendix.

We can think of one example where the local transverse susceptibility and hence P_{pq} is likely to be large at an impurity. This is FeMn where measurements by Jaccarino et al (1964) showed that the local hyperfine field had a very different temperature dependence from that of the host. This suggests that the local moment is only loosely coupled to the host moments. Jaccarino et al (1964) found that molecular field theory gave a surprisingly good fit to the magnetisations obtained from the experimental hyperfine field. It should therefore be possible to apply the molecular field estimate for P_{pq} (equation (3.42)) to this case. If the impurity moment-host moment coupling is weak, this suggests that $J_I(0)$ is small and hence P_{pq} will be large. A more accurate estimate might be obtained from the theory of Campbell and Gomés (1967) which has recently been shown to give very good results for the impurity moment (Kajzer and Parete 1980).

CHAPTER 4

QUADRUPOLE EFFECTS IN $GdAl_2$ 4A. Experimental Results

Degani and Kaplan (1973) measured a sizeable temperature dependent quadrupole interaction at aluminium ions in the rare earth intermetallic $GdAl_2$. They showed that the interaction varied linearly with the magnetisation over a wide range of temperature, 4K to 112K, and commented that most origins of a magnetisation dependent electric field gradient would have a quadratic variation. In this chapter we look at various mechanisms that would be consistent with their observations, particularly the pseudoquadrupole effect proposed as an explanation by Zevin and Kaplan (1975).

$GdAl_2$ has the cubic Laves phase structure depicted in figure 4 (Wernick and Geller 1960). Gadolinium ions are arranged on a diamond lattice and the aluminium ions form tetrahedra of point symmetry $\bar{3}m$ whose axes of symmetry are parallel to the principal diagonals of the cubic unit cell. The cell contains eight gadolinium and sixteen aluminium ions and the length of one side is $a_0 = 7.9\text{\AA}$.

Below $T_c = 176K$, the gadolinium ions order ferromagnetically along the $[1\ 1\ 1]$ direction, distinguishing aluminium ions at 'a' sites whose threefold symmetry axes coincide with the magnetisation vector from those at 'b' sites whose symmetry axes are parallel to $[\bar{1}\ 1\ 1]$, $[1\ \bar{1}\ 1]$ and $[1\ 1\ \bar{1}]$. Measurements of the echo decay modulation frequencies at the 'a' site shown in figure 4 were found to differ significantly

Fig. 4 Schematic representation of cubic Laves phase structure of GdAl_2 . The small open circles are the Al ions, the small full circles the Gd ions on one sublattice and the large open circles the Gd ions on the other sublattice. One 'a' site and 3 'G' sites are marked.

Fig. 5 The six nearest neighbour Al ions to a given Al ion. The dotted line marked the $[1\ 1\ 1]$ axis of the cubic unit cell of GdAl_2 .

from those at the 'b' sites marked and to show a magnetisation dependence, an effect that may be explained by the assumption of a magnetically induced field gradient (efg). (Degani and Kaplan 1973). They find, from 'a' site measurements that the quadrupole parameter P is given by (defining P_c and P_m from this equation),

$$|P| = P_c - \frac{M}{M_0} P_m \quad (4.1)$$

where

$$P_c = 0.314 \pm 0.001 \text{ MHz} \quad (4.2)$$

$$P_m = 0.043 \pm 0.004 \text{ MHz} \quad (4.3)$$

$$P = \frac{3e^2 Qq}{4I(2I-1)} \quad (4.4)$$

Q is the nuclear electrostatic quadrupole moment, q the efg and M_0 the saturation magnetisation.

The value of $|P|$ was measured in the para-magnetic phase by Jones and Budnick (1966) and was similar to P_c :

$$|P_{\text{para}}| = 0.320 \text{ MHz} \quad (4.5)$$

No change of P_{para} with temperature was reported for their measurements which were taken between 350K and 575K. Jaccarino et al (1960) measured the quadrupole interaction at aluminium ions in the chemically similar but non-magnetic compound LaAl_2 but do not mention a temperature variation there either. It seems likely then that in GdAl_2 magnetic effects are responsible for the temperature dependence of the quadrupole parameter as Degani and Kaplan (1973) suggested.

4B. The Pseudoquadrupole Effect

The pseudoquadrupole effect is clearly a good candidate

diamond lattice). The result follows from the assumption of exchange interactions between nearest neighbour ions and the fact that $\{S\} = -\{t\}$ for the $GdAl_2$ structure.

We evaluate P_{pq} from equations (2.30), (2.31), (4.7) and (4.9) using the following figures: $g_I = 1.46$ (Kittel 1971), $B_0 = 4.6T$ (Jones and Budnick (1966)) and we estimated $J(0)$ from $T_c = 176K$ (Degani and Kaplan (1973)) using molecular field theory. This gives

$$P_m = .44 \text{ KHz} \quad (4.10)$$

by comparison with Degani and Kaplan's (1973) measurement of 43kHz (equation (4.4)). This P_m from our calculations is very much smaller than the value measured by Degani and Kaplan (1973). We conclude that the observed temperature dependent quadrupole interaction is not due to the pseudoquadrupole effect.

Our results may be compared with Zevin and Kaplan (1975) who estimate P_m as 22kHz. Their much larger estimate which we consider an overestimate comes from approximations in the spin wave sums when evaluating

$$P^{pseudo} = \frac{A_z^2}{N^2} \sum_{K \neq K'} \frac{M_K}{E_K - E_{K'}} \quad (4.11)$$

where A_z is the magnetic hyperfine constant in the z direction (equation (8) of their paper). (As is clear from equation

(3.18) this is equivalent to

$$P_{pq} = \frac{A_c^2}{2\mu_0} X^{22} \quad (4.12)$$

in our notation). We calculated a value of $\tilde{\eta}$ that would give their estimate for P^{pseudo} and showed that it was 6π (cf 0.73).

They also appear to overestimate the hyperfine constant A_0 by a factor of 2.

4C. Other Mechanisms Consistent with Experiment

Single ion magnetostriction (as distinct from exchange magnetostriction - for a review see Kanamori (1963)) may provide an alternative mechanism. The distortion and hence the efg, q_m varies by symmetry arguments (Kanamori (1963)) as $\langle (S^z)^2 - \frac{1}{3} S(S+1) \rangle$ and vanishes above T_c in a cubic magnet, where q_m is the magnetostrictive contribution term to the total efg

We therefore assume that

$$q_m = q_m(T=0) \times \frac{\langle (S^z)^2 - \frac{1}{3} S(S+1) \rangle_T}{\langle (S^z)^2 - \frac{1}{3} S(S+1) \rangle_{T=0}} \quad (4.13)$$

Using non interacting spin wave theory it is easily shown

$$\langle (S^z)^2 - \frac{S(S+1)}{3} \rangle = \frac{2}{3} S(S+1) - \langle S_{\underline{i}}^- S_{\underline{i}}^+ \rangle - \langle S_{\underline{i}}^z \rangle \quad (4.14)$$

$$= S(2S-1) \left[-\frac{2}{3} + \langle \frac{S^z}{S} \rangle \right] \quad (4.14a)$$

since

$$\langle S_{\underline{i}}^- S_{\underline{i}}^+ \rangle = 2S \sum_{\underline{k}} n_{\underline{k}} \quad (4.15)$$

$$= 2(S - \langle S^z \rangle) \quad (4.15a)$$

Thus we obtain a linear variation of q with the magnetisation, in accordance with Degani and Kaplan's observations (using equation (4.4)). To calculate P_m , the rate at which P would change with $\langle S^z \rangle$ from this mechanism, we need to evaluate the efg at $T = 0$ so that we may find $q_m(T)$ and hence P from (4.4).

The magnitude of the efg at an 'a' site aluminium ion may

be estimated using the Thomas Fermi approximation for the potential of point charges screened by conduction electrons:

$$V(r) = \frac{e^{-k_0 r}}{r} \quad (4.16)$$

where

$$k_0^2 = \frac{e^2 m k_f}{h^2 \pi^2 \epsilon_0} \quad (4.17)$$

(Kittel 1971).

We investigate the reasonableness of this model by first looking at the efg in the paramagnetic phase, q_p . We consider nearest neighbour aluminium ions only as the screening length k_0^{-1} is small ($\sim 0.2 \text{ \AA}$). These ions are at the corners of two tetrahedra (see figure 5)*. We find that our calculated value for q_p ,

$$q_{p \text{ calc}} = 6(1 - \gamma_\infty) \frac{e^{-k_0 r_0}}{r_0^3} \left(\frac{2}{3} (k_0 r_0)^2 + k_0 r_0 + 1 \right) \quad (4.18)$$

Here γ_∞ is the Sternheimer antishielding factor and r_0 the nearest neighbour Al-Al distance. Taking $\gamma_\infty \sim 100$ (Cohen and Reif (1957), $Q = 0.15$ Barns (Sharma 1970), $z = 3$ and $r = \sqrt{2}/4 a_0$ where $a_0 = 7.9 \text{ \AA}$ (Wernick and Geller 1960) we obtain

$$|P_{\text{para}}| = 3.4 \text{ MHz} \quad (4.19)$$

Whilst this figure is too large by an order of magnitude of Jones and Budnick's (1966) measurement, the agreement is reasonable considering the approximations made and so we use this approach to calculate the efg in the ordered phase from the magnetostriction, q_m

We assume that the efg from magnetostriction,

$$q_m = q_{p \text{ expt}} \times q_{m \text{ calc}} / q_{p \text{ calc}} \quad (4.20)$$

where

$$\frac{q_{m \text{ calc}}}{q_{p \text{ calc}}} = \frac{[z(k_0 r_0)^3 + (k_0 r_0)^2 - 3(k_0 r_0) - 3] \epsilon}{4(k_0 r_0)^2 + 6(k_0 r_0) + 6} \quad (4.20a)$$

where q_{pexpt} is the experimental value of q_p . (4.20a) is obtained by assuming q_m is given by the linear term in a Taylor expansion $q_m(\epsilon)$, where ϵ is the strain from magnetostriction.

$$P_{pq}^{ms} = |P_{para}| \frac{q_{mcalc}^3}{q_{calc}} \quad (4.21)$$

$$\text{giving } P_{pq}^{ms} = 54.3 \text{ Hz, using (4.13) and} \quad (4.22)$$

$$\epsilon = 26.10^{-6} \quad (\text{Burd and Lee 1977})$$

This calculation suggests that single ion magnetostriction is too small to account for the temperature dependent quadrupole interaction measured by Degani and Kaplan (1973).

Another possible explanation is that there is no magnetisation dependent quadrupole interaction and that the temperature dependence seen is due to lattice expansion. This is because both the magnetisation* and variation of q with T due to thermal expansion go as $T^{3/2}$ over a wide range of temperature, $.02T/T_c$ to about $.6T/T_c$ in both cases. Christiansen et al (1976) showed that the following relationship is valid in a very wide range of non cubic metals and intermetallics:

$$q(T) = q(0) (1 - BT^{3/2}) \quad (4.23)$$

where

$$B \sim 10^{-5} \text{ K}^{-3/2} \quad (4.24)$$

B was generally positive, only one case (^{181}Ta in Be) being found where it was negative. In GdAl_2 the aluminium ions are at non cubic sites so that they do see a quadrupole moment due to the lattice. We used the data of Degani and Kaplan (1973) to find B on the basis that the temperature variation of the efg were entirely due to lattice expansion and discovered that B would be of the right order of magnitude.

*Nesbitt et al (1962)

We also showed using equations (4.4) and (4.23) that the quadrupole parameter P would increase from MHz at 350K to MHz at 575K whereas Jones and Budnick (1966) report $P = 0.32$ MHz for the range 350 to 575K. Furthermore this explanation does not account for the difference in observations at 'a' and 'b' sites discussed in section A, nor the lack of temperature dependence of the quadrupole splitting in LaAl_2 , also discussed in section A. Thus this explanation, though it accounts neatly for the linearity of the efg with magnetisation over the large temperature range of 4K to 112K, is unlikely to be valid.

We also considered volume striction. As the crystal expands, the efg at the aluminium sites responsible for the lattice contribution to the lattice coupling constant q will change. In this case the predicted temperature dependence would be that of the magnetic energy namely $T^{5/2}$ in simple spin wave theory. Thus the quadrupole splitting would have varied as $(M(T))^{5/2}$ where $M(T)$ is the magnetisation rather than having the observed linearity. We have therefore not investigated this line further.

CHAPTER 5CONCLUSIONS

We have shown that the pseudoquadrupole effect may be written in terms of the difference between the local transverse and longitudinal susceptibilities and the square of the hyperfine field. These susceptibilities can be calculated exactly at $T = 0$ for a localised (Heisenberg) spin model and estimated for the localised model at higher temperatures. They can also be calculated within the itinerant model for which we have given a simple theory.

We have used our itinerant theory to find estimates of the pseudoquadrupole parameter P_{pq} in pure iron and nickel and we have shown that P_{pq} is three orders of magnitude down from the experimentally measured quadrupole splitting P_e for iron. Our estimates for both iron and nickel suggest that in neither case is the effect likely to be experimentally observable, given an error of about 80% for P_e quoted in the measurements on iron.

We have extended our theory to look at dilute impurities in iron and nickel. For isotopes of iridium in iron and nickel we find that here too P_{pq} is several orders of magnitude less than values of P_e and we can show that for iridium in nickel, P_e is not significantly influenced by the pseudoquadrupole effect. However, our estimate of P_{pq} at cobalt impurities in iron is less than P_e by a factor of three only, so a more accurate theory is required to establish whether the pseudoquadrupole effect may be observable here. We also

consider that P_{pq} may be large at manganese in iron although we do not estimate its size.

In the rare earth intermetallic magnet with localised moments, $GdAl_2$, we have shown that the pseudoquadrupole effect is too small to account for the observed temperature dependent quadrupole splitting.

Our theory has been given for cubic ferromagnets but it may readily be extended to cubic antiferromagnets or any other colinear spin structure. We do not consider non cubic materials, as here the electric field gradients are large. Thus the pseudoquadrupole effect would generally be very much less than the 'real' quadrupole effects due to the electrostatic quadrupole moment of the nucleus.

Finally we note that the following conditions are favourable for an observation of the pseudoquadrupole effect in cubic magnets:

- (i) A large value of the hyperfine constant
- (ii) A small magnetically induced electric field gradient
- (iii) A low value of the exchange constant J
- (iv) Two isotopes (a) and (b) as dilute impurities in the same host such that the ratios of pseudoquadrupole to real quadrupole parameters

$$R = \frac{A_a^2 Q_v I_a (2I_a - 1)}{A_b^2 Q_a I_v (2I_v - 1)} \quad (5.1)$$

is large. Here A is the hyperfine constant for the two different isotopes, Q the nuclear quadrupole moment and I the nuclear

spin.

Looyestijn et al (1979) have observed the pseudoquadrupole effect as a function of magnetic field for ^{17}O in $\text{Rb}_2\text{CuCl}_4 \cdot 2\text{H}_2\text{O}$ in the paramagnetic phase. Here condition (iii) applies.
